SUMMARY
JavaScript is a popular programming language that is also error-prone due to its asynchronous, dynamic, and loosely-typed nature. In recent years, numerous techniques have been proposed for analyzing and testing JavaScript applications. However, our survey of the literature in this area revealed that the proposed techniques are often evaluated on different datasets of programs and bugs. The lack of a commonly used benchmark limits the ability to perform fair and unbiased comparisons for assessing the efficacy of new techniques. To fill this gap, we propose BUGSJS, a benchmark of 453 real, manually validated JavaScript bugs from 10 popular JavaScript server-side programs, comprising 444k LOC in total. Each bug is accompanied by its bug report, the test cases that expose it, as well as the patch that fixes it. We extended BUGSJS with a rich web interface for visualizing and dissecting the bugs’ information, as well as a programmable API to access the faulty and fixed versions of the programs and to execute the corresponding test cases, which facilitates conducting highly-reproducible empirical studies and comparisons of JavaScript analysis and testing tools. Moreover, following a rigorous procedure, we performed a classification of the bugs according to their nature. Our internal validation shows that our taxonomy is adequate for characterizing the bugs in BUGSJS. We discuss several ways in which the resulting taxonomy and the benchmark can help direct researchers interested in automated testing of JavaScript applications.

KEY WORDS: JavaScript, bug database, benchmark, reproducibility, bug taxonomy, BUGSJS

1. INTRODUCTION
JavaScript (JS) is the de-facto web programming language globally,† and the most adopted language on GitHub.‡ JavaScript is massively used in the client-side of web applications to achieve high responsiveness and user friendliness. In recent years, due to its flexibility and effectiveness, it has been increasingly adopted also for server-side development, leading to full-stack web applications [1]. Platforms such as Node.js§ allow developers to conveniently develop both the front- and back-end of the applications entirely in JavaScript.

Despite its popularity, the intrinsic characteristics of JavaScript—such as weak typing, prototypal inheritance, and run-time evaluation—make it one of the most error-prone programming languages. As such, a large body of software engineering research has focused on the analysis and testing of JavaScript web applications [2, 3, 4, 5, 6, 7, 8, 9].

Existing research techniques are typically evaluated through empirical methods (e.g., controlled experiments), which need software-related artifacts, such as source code, test suites, and descriptive bug reports. To date, however, most of the empirical works and tools for JavaScript have been evaluated on different datasets of subjects. Additionally, subject programs or accompanying experimental data are rarely made available in a detailed, descriptive, curated, and coherent manner. This not only hampers the reproducibility of the studies themselves, but also makes it difficult for researchers to assess the state-of-the-art of related research and to compare existing solutions.

Specificaly, testing techniques are typically evaluated with respect to their effectiveness at detecting faults in existing programs. However, real bugs are hard to isolate, reproduce and characterize. Therefore, the common practice relies on manually-seeded faults, or mutation testing [10]. Each of these solutions has limitations. Manually-injected faults can be biased toward researchers’ expectations, undermining the representativeness of the studies that use them. Mutation techniques, on the other hand, allow generating a large number of “artificial” faults. Although research has shown that mutants are quite representative of real bugs [11, 12, 13], mutation testing is computationally expensive to use in practice. For these reasons, benchmarks of manually validated bugs are of paramount importance for devising novel debugging, fault localization, or program repair approaches.

Several benchmarks of bugs have been proposed and largely utilized by researchers to advance testing research. Notable instances are the Software-artifact Infrastructure Repository [14], Defects4J [15], ManyBugs [16], and BugSwarm [17]. Purpose-specific test and bug datasets also exist to support studies in program repair [18], test generation [19], and security [20]. However, to date, a well-organized repository of labeled JavaScript bugs is still missing. The plethora of different JavaScript implementations available (e.g., V8, JavaScriptCore, Rhino) further makes devising a cohesive bugs benchmark nontrivial.

In our previous work [21], we presented BUGSJS, a benchmark of 453 JavaScript-related bugs from 10 open-source JavaScript projects, based on Node.js and the Mocha testing framework. BUGSJS features an infrastructure containing detailed reports about the bugs, the faulty versions of programs, the test cases exposing them, as well as the patches that fix them.

This article is a revised and expanded version of our conference paper [21]. We provide details on the differences between the prior paper and this article. From the technical standpoint, first we added a port “dissection” to BUGSJS, i.e., a web interface to inspect/query information about the bugs. Second, we enriched the API with the possibility of conducting more fine-grained analysis with an optimized command that retrieves the coverage for each individual test (per-test coverage). We also added more precomputed data from the source code, test cases and executions to better facilitate related research. Concerning the intellectual contributions, we performed a classification of the bugs in BUGSJS, which was missing in the initial conference paper. We constructed our taxonomy using faceted classification [22], i.e., we created the categories/subcategories of our taxonomy in a bottom-up fashion, by analyzing different sources of information about the bugs.

This article makes the following contributions:

Survey A survey of the previous work on analysis and testing of JavaScript applications, revealing the lack of a comprehensive benchmark of JavaScript programs and bugs to support empirical evaluation of the proposed techniques.

Dataset BUGSJS, a benchmark of 453 manually selected and validated JavaScript bugs from 10 JavaScript Node.js programs pertaining to the Mocha testing framework.

Framework A Docker-based infrastructure to download, analyze, and run test cases exposing each bug in BUGSJS and the corresponding real fixes implemented by developers. The infrastructure includes a web-based dashboard and a set of precomputed data from the subjects and tests as well.
Taxonomy A qualitative analysis of BUGSJS resulting in a bug taxonomy of server-side JavaScript bugs, which, to our knowledge, is the first of this kind.

Evaluation A quantitative and qualitative analysis of the bug-fixes related to the BUGSJS bugs in relation to existing classification schemes.

2. STUDIES ON JAVASCRIPT ANALYSIS AND TESTING

To motivate the need for a novel benchmark for JavaScript bugs, we surveyed the works related to software analysis and testing in the JavaScript domain. Our review of the literature also allowed us to gain insights about the most active research areas in which our benchmark should aim to be useful.

In the JavaScript domain, the term benchmark commonly refers to collections of programs used to measure and test the performance of web browsers with respect to the latest JavaScript features and engines. Instances of such performance benchmarks are JetStream, Kraken, Dromaeo, Octane, and V8. In this work, however, we refer to benchmark as a collection of JavaScript programs and artifacts (e.g., test cases or bug reports) used to support empirical studies (e.g., controlled experiments or user studies) related to one or more research areas in software analysis and testing.

We used the databases of scientific academic publishers and popular search engines to look for papers related to different software analysis and testing topics for JavaScript. We adopted various combinations of keywords: JavaScript, testing (including code coverage measurement, mutation testing, test generation, unit testing, test automation, regression testing), bugs and debugging (including fault localization, bug and error classification), and web. We also performed a lightweight forward and backward snowballing to mitigate the risk of omitting relevant literature. Last, we examined the evaluation section of each paper. We retained only papers in which real-world, open-source JavaScript projects were used, whose repositories and versions could be clearly identified. This yielded 25 final papers. Nine of these studies are related to bugs, in which 670 subjects were used in total. The remaining 16 papers are related to other testing fields, comprising 494 subjects in total.

In presenting the results of our survey of the literature, we distinguish (1) studies containing specific bug information and other artifacts (such as source code and test cases), and (2) studies containing only JavaScript programs and other artifacts not necessarily related to bugs.

2.1. Bug-related Studies for JavaScript

We analyzed papers using JavaScript systems that include bug data in greater detail, because these works can provide us important insights about the kind of analysis researchers used the subjects for, and thus, the requirements that a new benchmark of bugs should adhere to.

We found nine studies in this category. Ocariza et al. [5] present an analysis and classification of bug reports to understand the root causes of client-side JavaScript faults. This study includes 502 bugs from 19 projects with over 2M LOC. The results of the study highlight that the majority (68%) of JavaScript faults are caused by faulty interactions of the JavaScript code with the Document Object Model (DOM). Moreover, most JavaScript faults originate from programmer mistakes committed in the JavaScript code itself, as opposed to other web application components.

Another bug classification presented by Gao et al. [24] focuses on type system-related issues in JavaScript (which is a dynamically typed language). The study includes about 400 bug reports from 398 projects with over 7M LOC. The authors ran a static type checker such as Facebook’s Flow.”

https://github.com/hakobera/node-v8-benchmark-suite
https://flow.org/
or Microsoft’s TypeScript† on the faulty versions of the programs. On average, 60 out of 400 bugs were detected (15%), meaning they may have been avoided in the first place if a static type checker were used to warn the developer about the type-related bug.

Hanam et al. [25] present a study of cross-project bug patterns in server-side JavaScript code, using 134 Node.js projects of about 2.5M LOC. They propose a technique called BugAID for discovering such bug patterns. BugAID builds on an unsupervised machine learning technique that learns the most common code changes obtained through AST differencing. Their study revealed 219 bug fixing change types and 13 pervasive bug patterns that occur across multiple projects. In our evaluation, we conduct a thorough comparison with Hanam et al.’s taxonomy.

Ocariza et al. [26] propose an inconsistency detection technique for MVC-based JavaScript applications which is evaluated on 18 bugs from 12 web applications (7k LOC). A related work [27] uses 15 bugs in 20 applications (nearly 1M LOC). They also present an automated technique to localize JavaScript faults based on a combination of dynamic analysis, tracing, and backward slicing, which is evaluated on 20 bugs from 15 projects (14k LOC) [28]. Also, their technique for suggesting repairs for DOM-based JavaScript faults is evaluated on 22 bugs from 11 applications (1M LOC) [29].

Wang et al. [4] present a study on 57 concurrency bugs in 53 Node.js applications (about 3.5M LOC). The paper proposes several different analyses pertaining to the retrieved bugs, such as bug patterns, root causes, and repair strategies. Davis et al. [30] propose a fuzzing technique for identifying concurrency bugs in server-side event-driven programs, and evaluate their technique on 12 real world programs (around 216k LOC) and 12 manually selected bugs.

2.2. Other Analysis and Testing Studies for JavaScript

Empirical studies in software analysis and testing benefit from a large variety of software artifacts other than bugs, such as test cases, documentation, or code revision history. In this section, we briefly describe the remaining papers of our survey.

Milani Fard and Mesbah [31] characterize JavaScript tests in 373 JavaScript projects according to various metrics, e.g., code coverage, test commits ratio, and number of assertions.

Mirshokraie et al. propose several approaches to JavaScript automated testing. This includes an automated regression testing based on dynamic analysis, which is evaluated on nine web applications [32]. The authors also propose a mutation testing approach, which is evaluated on seven subjects [33], and on eight applications in a related work [34]. They also propose a technique to aid test generation based on program slicing [35], where unit-level assertions are automatically generated for testing JavaScript functions. Seven open-source JavaScript applications are used to evaluate their technique. The authors also present a related approach for JavaScript unit test case generation, which is evaluated on 13 applications [36].

Adamsen et al. [37] present a hybrid static/dynamic program analysis method to check code coverage-based properties of test suites from 27 programs. Dynamic symbolic execution is used by Milani Fard et al. [38] to generate DOM-based test fixtures and inputs for unit testing JavaScript functions, and four experimental subjects are used for evaluation. Ermuth and Pradel propose a GUI test generation approach [6], and evaluate it on four programs.

Artzi et al. [39] present a framework for feedback-directed automated test generation for JavaScript web applications. In their study, the authors use 10 subjects. Mesbah et al. [40] present Atusa, a test generation technique for Ajax-based applications which they evaluate on six web applications. A comprehensive survey of dynamic analysis and test generation for JavaScript is presented by Andreasen et al. [41].

Billes et al. [2] present a black-box analysis technique for multi-client web applications to detect concurrency errors on three real-world web applications. Hong et al. [42] present a testing framework to detect concurrency errors in client-side web applications written in JavaScript, and use five real-world web applications.

Wang et al. [3] propose a modification to the delta debugging approach that reduces the event trace, which is evaluated on 10 real-world JavaScript application failures. Dhok et al. [43] present a concolic testing approach for JavaScript which is evaluated on 10 subjects.

2.3. Findings

In the surveyed papers, we observed that the proposed techniques were evaluated using different sets of programs, with little to no overlap.

Table I shows the program distribution per paper. In bug-related studies, 633 subject programs were adopted overall, with 607 of these programs (96%) were used in only one study, and no subject was used in more than four papers (Table I, columns 1 and 2). Other studies exhibit the same trend (Table I, columns 3 and 4): overall, 1,164 subjects were used in all the investigated papers, of which 1,023 were unique. From these, 910 (89%) were used in only one paper, and no subject was used in more than five papers.

In conclusion, we observe that the investigated studies involve different sets of programs, since no centralized benchmark is available to support reproducible experiments in analysis and testing related to JavaScript bugs.

To devise a centralized benchmark for JavaScript bugs that enables reproducibility studies in software analysis and testing, we considered the insights and guidelines provided by existing similar datasets (e.g., Defects4J [15]), as well as the knowledge gained from our study of the literature on empirical experiments using JavaScript programs and bugs.

First, the considered subject systems should be real-world, publicly available open-source JavaScript programs. To ensure representativeness of the benchmark, they should be diverse in terms of the application domain, size, development, testing, and maintenance practices (e.g., the use of continuous integration (CI), or code review process).

Second, the buggy versions of the programs must have one or more test cases available demonstrating each bug. The bugs must be reproducible under reasonable constraints; this excludes non-deterministic or flaky features.

Third, the versions of the programs in which the bugs were fixed by developers, i.e., the patches, must be also available. Typically, when a bug is fixed, new unit tests are also added (often in the same bug-fixing commit) to cover the buggy feature, allowing for better regression testing. This allows extracting the bug-fixing changes, e.g., by diffing the buggy and fixed revisions.

Additionally, the benchmark should include the bug report information, including critical times (e.g. when the bug was opened, closed, or reopened), the discussions about each bug, and link to the commits where the bug was fixed.

To fill this gap, in Section 3 we overview BugsJS [21], a benchmark of real JavaScript bugs, its design and implementation.
3. BUGSJS – THE PROPOSED BENCHMARK

To construct a benchmark of real JavaScript bugs, we identify existing bugs from the programs’ version control histories, and collect the real fixes provided by developers. Developers often manually label the revisions of the programs in which reported bugs are fixed (bug-fixing commits, or patches). As such, we refer to the revision preceding the bug-fixing commit as the buggy commit. This allowed us to extract detailed bug reports and descriptions, along with the buggy and bug-fixing commits they refer to. Particularly, each bug and fix should adhere to the following properties:

- **Reproducibility.** One or more test cases are available in a buggy commit to demonstrate the bug. The bug must be reproducible under reasonable constraints. We excluded non-deterministic features and flaky tests from our study, since replicating them in a controlled environment would be excessively challenging.

- **Isolation.** The bug-fixing commit applies to JavaScript source code files only; changes to other artifacts such as documentation or configuration files are not considered. The source code of each commit must be cleaned from irrelevant changes (e.g., feature implementations, refactorings, changes to non-JavaScript files). The isolation property is particularly important in research areas where the presence of noise in the data has detrimental impacts on the techniques (e.g., automated program repair, or fault localization approaches).

![Figure 1. Overview of the bug selection and inclusion process.](image)

Figure 1 depicts the main steps of the process we performed to construct our benchmark. First, we adopted a systematic procedure to select the JavaScript subjects to extract the bug information from 1. Then, we collected bug candidates from the selected projects 2, and manually validated each bug for inclusion by means of multiple criteria 3. Next, we performed a dynamic sanity check to make sure that the tests introduced in a bug-fixing commit can detect the bug in the absence of its fix 4. Finally, the retained bugs were cleaned from irrelevant patches (e.g., whitespaces).

### 3.1. Subject Systems Selection

To select relevant programs to include in BUGSJS, we focused on popular and trending JavaScript projects on GitHub. Such projects often engage large communities of developers, and therefore, are more likely to follow software development best practices, including bug reporting and tracking. Moreover, GitHub’s issue IDs allow conveniently connecting bug reports to bug-fixing commits.

Popularity was measured using the projects’ Stargazers count (i.e., the number of stars owned by the subject’s GitHub repository). We selected server-side Node.js applications which are popular (Stargazers count ≥ 100) and mature (number of commits > 200), and have been actively maintained (year of the latest commit ≥ 2017). We currently focus on Node.js because it is emerging as one of the most pervasive technologies to enable using JavaScript in the server side, leading to the so-called full-stack web applications [1]. Limiting the subject systems to server-side applications and specific testing frameworks is due to technological constraints, as running tests for browser-based programs would require managing many complex and time-consuming configurations. We discuss the potential implications of this constraint in Section 6.

We examined the GitHub repository of each retrieved subject system to ensure that bugs were properly tracked and labeled. Particularly, we only selected projects in which bug reports had a

</table>

dedicated issue label on GitHub’s Issues page, which allows filtering irrelevant issues (pertaining to, e.g., feature requests, build problems, or documentation), so that only actual bugs are included. Our initial list of subjects included 50 Node.js programs, from which we filtered out projects based on the number of candidate bugs found and the adopted testing frameworks.

3.2. Bugs Collection

Collecting bugs and bug-fixing commits. For each subject system, we first queried GitHub for closed issues assigned with a specific bug label using the official GitHub’s API. For each closed bug, we exploit the links existing between issues and commits to identify the corresponding bug-fixing commit. GitHub automatically detects these links when there is a specific keyword (belonging to a predefined list†), followed by an issue ID (e.g., Fixes #14).

Each issue can be linked to zero, one, or more source code commits. A closed bug without a bug-fixing commit could mean that the bug was rejected (e.g., it cannot be replicated), or that developers did not associate that issue with any commit. We discarded such bugs from our benchmark, as we require each bug to be identifiable by its bug-fixing commit. At last, similarly to existing benchmarks [15], we discarded bugs linked to more than one bug-fixing commit, as this might imply that they were fixed in multiple steps, or that the first attempt for fixing them was unsuccessful.

Including corresponding tests. We require each fixed bug to have unit tests that demonstrate the absence of the bug. To meet this requirement, we examined the bug-fixing patches to ensure they also contain changes or additions in the test files. For this filtering, we manually examined each patch to determine whether test files were involved. The result of this step is the list of bug candidates for the benchmark. From the initial list of 50 subject systems, we considered the projects having at least 10 bug candidates.

Testing frameworks. There are several testing frameworks available for JavaScript applications. We collected statistics about the testing frameworks used by the 50 considered JavaScript projects. Our results show that there is no single predominant testing framework for JavaScript (as compared to, for instance, JUnit which is used by most Java developers). We found that the majority of tests in our pool were developed using Mocha‡ (52%), Jasmine§ (10%), and QUnit¶ (8%). Consequently,

[§https://mochajs.org/](https://mochajs.org/)
[¶https://jasmine.github.io/](https://jasmine.github.io/)
[¶https://qunitjs.com/](https://qunitjs.com/)
the initial version of BUGSJS only includes projects that use Mocha, whose prevalence as JavaScript testing framework is also supported by a recent large-scale empirical study [31].

**Final Selection.** Table II reports the names and descriptive statistics of the 10 applications we ultimately retained. Notice that all these applications have at least 1000 LOC (frameworks excluded), thus being representative of modern web applications (Ocariza et al. [5] report an average of 1,689 LOC for AngularJS web applications on GitHub with at least 50 stars).

The subjects represent a wide range of domains. **Bower** is a front-end package management tool that exposes the package dependency model through an API. **Express** is a minimal and flexible Node.js web application framework that provides a robust set of features for web and mobile applications. **Hessian.js** is a JavaScript binary web service protocol that makes web services usable without requiring a large framework, and without learning a new set of protocols. **Hexo** is a blog framework powered by Node.js. **Karma** is a popular framework agnostic test runner tool for JavaScript. **Mongoose** is a MongoDB object modeling tool for Node.js. **Node-redis** is a Node.js client for Redis database. **Pencilblue** is a CMS and blogging platform, powered by Node.js. **Shields** is a web service for badges in SVG and raster format.

### 3.3. Manual Patch Validation

We manually investigated each bug and the corresponding bug-fixing commit to ensure that only bugs meeting certain criteria are included, as described below.

<table>
<thead>
<tr>
<th>Rule Name</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>Isolation</td>
<td>The bug-fixing changes must fix only one (1) bug (i.e., must close exactly one (1) issue)</td>
</tr>
<tr>
<td>Complexity</td>
<td>The bug-fixing changes should involve a limited number of files ($\leq 3$), lines of code ($\leq 50$) and be understandable within a reasonable amount of time (max 5 minutes)</td>
</tr>
<tr>
<td>Dependency</td>
<td>If a fix involves introducing a new dependency (e.g., a library), there must also exist production code changes and new test cases added in the same commit</td>
</tr>
<tr>
<td>Relevant Changes</td>
<td>The bug-fixing changes must involve only changes in the production code that aim at fixing the bug (whitespace and comments are allowed)</td>
</tr>
<tr>
<td>Refactoring</td>
<td>The bug-fixing changes must not involve refactoring of the production code</td>
</tr>
</tbody>
</table>

**Methodology.** Two authors of this paper manually investigated each bug and its corresponding bug-fixing commit and labeled them according to a well-defined set of inclusion criteria (Table III). The bugs that met all criteria were initially marked as “Candidate Bug” to be considered for inclusion.

In detail, for each bug, the authors investigated simultaneously the code of the commit to ensure relatedness to the bug being fixed. During the investigation, however, several bug-fixing commits were too complex to comprehend by the investigators, either because domain knowledge was required, or because the number of files or lines of code being modified was large. We labeled such complex bug-fixing commits as “Too complex”, and discarded them from the current version of BUGSJS. The rationale is to keep the size of the patches within reasonable thresholds, so as to select a high quality corpus of bugs which can be easily analyzable and processable by both manual inspection and automated techniques. Particularly, we deemed a commit being too complex if the production code changes involved more than three (3) files or more than 50 LOC, or if the fix required more than 5 minutes to understand. In all such cases, a discussion was triggered among the authors, and the case was ignored if the authors unanimously decided that the fix was too complex.

Another case for exclusion is due to refactoring operations in the analyzed code. First, our intention was to keep the original code’s behaviour as written by developers. As such, we only restored modifications that did not affect the program’s behavior (e.g., whitespaces). Indeed, in many cases, in-depth domain knowledge is very much required to decouple refactoring and bug fixation. JavaScript is a dynamic language, and code can be refactored in many ways. Thus, it is more challenging to observe and account for side-effects only by looking at the code than, for instance, in Java. In addition, refactoring may affect multiple parts of a project, it affects metrics such as code coverage, and it makes restoring the original code changes more challenging.

</table>

Results. Overall, we manually validated 795 commits (i.e., bug candidates), of which 542 (68.18 \%) fulfilled the criteria. Table IV (Manual) illustrates the result of this step for each application and across all applications.

The most common reason for excluding a bug is that the fix was deemed as too complex (136). Other frequent scenarios include cases where a bug-fixing commit addressed more than one bug (32), or where the fix did not involve production code (29), or contained refactoring operations (39). Also, we found four cases in which the patch did not involve the actual test’s source code, but rather comments or configuration files.

3.4. Sanity Checking through Dynamic Validation

To ensure that the test cases introduced in a bug-fixing commit were actually intended to test the buggy feature, we adopted a systematic and automatic approach described next.

Methodology. Let V_{bug} be the version of the source code that contains a bug b, and let V_{fix} be the version in which b is fixed. The existing test cases in V_{bug} do not fail due to b. However, at least one test of V_{fix} should fail when executed on V_{bug}. This allows us to identify the test in V_{fix} used to demonstrate b (isolation) and to discard cases in which tests immaterial to the considered buggy feature were introduced.

To run the tests, we obtained the dependencies and set up the environment for each specific revision of the source code. Over time, however, developers made major changes to some of the projects’ structure and environment, making tests replication infeasible. These cases occurred, for instance, when older versions of required dependencies were no longer available, or when developers migrated to a different testing framework (e.g., from QUnit to Mocha).

For the projects that used scripts (e.g., grunt, bash, Makefile) to run their tests, we extracted them, so as to isolate each test’s execution and avoiding possible undesirable side effects caused by running the complete test suite.

Results. After the dynamic analysis, 453 bug candidates were ultimately retained for inclusion in BUGSJS (84\% of the 542 bug candidates from the previous step).

Table IV (Dynamic) reports the results for the dynamic validation phase. In 22 cases, we were unable to run the tests because dependencies were removed from the repositories. In 15 cases, the project at revision V_{bug} did not use Mocha for testing b. In 12 cases, tests were failing during the execution, whereas in 40 cases no tests failed when executed on V_{bug}. We excluded all such bug candidates from the benchmark.
3.5. Patch Creation

We performed manual cleaning on the bug-fixing patches, to make sure they only include changes related to bug fixes. In particular, we removed irrelevant files (e.g., *.md, .gitignore, LICENSE), and irrelevant changes (i.e., source code comments, when only comments changed, and comments unrelated to bug-fixing code changes, as well as changes solely pertaining to whitespaces, tabs, or newlines). Furthermore, for easier analysis, we separated the patches into two separate files, the first one including the modifications to the tests, and the second one pertaining to the production code fixes.

3.6. Final Benchmark Infrastructure and Implementation

**Infrastructure.** Figure 2 illustrates the overall architecture of BUGSJS, which supports common activities related to the benchmark, such as running the tests at each revision, or checking out specific commits. The framework’s command-line interface includes the following commands:

- **info:** Prints out information about a given bug.
- **checkout:** Checks-out the source code for a given bug.
- **test:** Runs all tests for a given bug and measures the test coverage.
- **per-test:** Runs each test individually and measures the per-test coverage for a given bug.

For the checkout, test, and per-test commands, the user can specify the desired code revision: buggy, buggy with the test modifications applied, or the fixed version. BUGSJS is equipped with a pre-built environment that includes the necessary configurations for each project to execute correctly. This environment is available as a Docker image along with a detailed step-by-step tutorial. The interested reader can find more information on BUGSJS and access the benchmark on our website:

https://bugsjs.github.io/

**Source code commits and tests.** We used GitHub’s fork functionality to make a full copy of the git history of the subject systems. The unique identifier of each commit (i.e., the commit SHA1 hashes) remains intact when forking. In this way, we were able to synchronize the copied fork with the original repository and keep it up-to-date. Importantly, our benchmark will not be lost if the original repositories get deleted.

The fork is a separate git repository; therefore, we can push commits to it. Taking advantage of this possibility, we have extended the repositories with additional commits, to separate the bug-fixing commits and their corresponding tests. To make such commits easily identifiable, we tagged them using the following notation (X denotes a sequential bug identifier):

![Figure 2. Overview of BUGSJS architecture](image-url)
• **Bug-X**: The parent commit of the revision in which the bug was fixed (i.e., the buggy revision);

• **Bug-X-original**: A revision with the original bug-fixing changes (including the production code and the newly added tests);

• **Bug-X-test**: A revision containing only the tests introduced in the bug-fixing commit, applied to the buggy revision;

• **Bug-X-fix**: A revision containing only the production code changes introduced to fix the bug, applied to the buggy revision;

• **Bug-X-full**: A revision containing both the cleaned fix and the newly added tests, applied to the buggy revision.

**Test runner commands.** For each project, we have included the necessary test runner commands in a CSV file. Each row of the file corresponds to a bug in the benchmark, and specifies:

1. A sequential bug identifier;
2. The test runner command required to run the tests;
3. The test runner command required to produce the test coverage results;
4. The Node.js version required for the project at the specific revision where the bug was fixed, so that the tests can execute properly;
5. The preparatory test runner commands (e.g., to initialize the environment to run the tests, which we call pre-commands);
6. The cleaning test runner commands (e.g., the tear down commands, which we call post-commands) to restore the application’s state.

**Bug report data.** Forking repositories does not maintain the issue data associated with the original repository. Thus, the links appearing in the commit messages of the forked repository still refer to the original issues. In order to preserve the bug reports, we obtained them via the GitHub’s API and stored them in the Google’s Protocol Buffers\(^{‡‡}\) format. Particularly, for each bug report, we store the original issue identifier paired with our sequential bug identifier, the text of the bug description, the issue open and close dates, the SHA1 of the original bug-fixing commit along with the commit date and commit author identifiers. Lastly, we save the comments from the issues’ discussions.

In the following, we list several artifacts that we added to BUGSJS in form of **precomputed data.**\(^*\)** These can be reproduced by performing suitable static and dynamic analyzes on the benchmark, however, we supply this information to better facilitate further bug-related research, including bug prediction, fault localization, automatic repair, etc.

**Test coverage data.** As part of the technical extensions to the initial version of the framework \([21]\), we included in BUGSJS pre-computed information. We used the tool Istanbul\(^††\) to compute per-test coverage data for Bug-X and Bug-X-test versions of each bug, and the results are available in the JSON format. Particularly, for each project, we included information about the tests of the Bug-X versions in a separate CSV file. Each row in such file contains the following information:

1. A sequential bug identifier;
2. Total LOC in the source code, as well as LOC covered by the tests;

\(^‡‡\)https://developers.google.com/protocol-buffers/
\(^*\)https://github.com/BugsJS/bug-dataset
\(^††\)https://istanbul.js.org/
3. The number of functions in the source code, as well as the number of functions covered by the tests;

4. The number of branches in the source code, as well as the number of branches covered by the tests;

5. The total number of tests in the test suite, along with the number of passing, failing and pending tests (i.e., the tests which were skipped due to execution problems).

**Static source code metrics.** Furthermore, to support studies based on source code metrics, we run static analysis on Bug-X-full and Bug-X versions of each bug. For the static analysis, we used the tool SourceMeter‡‡ which calculates 41 static source code metrics for JavaScript. The results are available in a zip file named metrics.

### 3.7. BugsJS Dissection

Sobreira et al. [44] implemented a web-based interface for the bugs in the Defects4J bug benchmark [15]. It presents data to help researchers and practitioners to better understand this bug dataset.‡ We also utilized this dashboard and ported Dissection to BugsJS (Figure 3), which is available on the BugsJS website:

[https://bugsjs.github.io/dissection](https://bugsjs.github.io/dissection)

BugsJS Dissection presents the information in the dataset to the user in an accessible and browsable format, which is useful for inspecting the various information related to the bugs, their fixes, their descriptions, and other artefacts such as the pre-computed metrics.

More precisely, information provided in BugsJS Dissection include:

1. # Files: number of changed files.
2. # Lines: number of changed lines.
3. # Added: number of added lines.

‡‡https://www.sourcemeter.com/
‡https://github.com/program-repair/defects4j-dissection
4. # Removed: number of removed lines.
5. # Modified: number of modified lines.
6. # Chunks: number of sections containing sequential line changes.
7. # Failing tests: number of failed test cases.
8. # Bug-fixing type: number of bug-fixing types based on the taxonomy by Pan et al. [45].

Inspection of the bugs is supported through different filtering mechanisms that are based on the bug taxonomy and bug-fix types. By clicking on a bug, additional details appear (Figure 4), including bug-fix types, the patch by the developers, taxonomy category and failed tests.

3.8. Extending BugsJS

BUGSJS was designed and implemented in a way that is easy to extend with new JavaScript projects, however, there are some restrictions. The current version of the framework only supports projects that are in a git repository and use the Mocha testing framework. If the project is hosted on GitHub, it can also be forked under the BUGSJS’s GitHub Organization to preserve the state of the repository.

Mining an appropriate bug to add to BUGSJS takes four steps as described at the beginning of Section 3. It is mainly manual work, but some of it could be done programmatically. In our case, we used GitHub as the source of bug reports, which has a public API, thus we could automate the bug collection step. Validating the bug-fixing patches requires manual work, but it can be partially supported by automation, e.g., for filtering patches that modify both the production code and the tests. However, in our experience during the development of BUGSJS, the location of test files varies across different projects, and sometimes across versions as well. Thus, it is still challenging to automatically determine it for an arbitrary set of JavaScript projects. Dynamic validation also requires some manual effort. Despite we limited the support only to the most common testing framework (Mocha), the command that runs the test suite is, in some cases, assembled at runtime (e.g., with grunt or Makefile) and can change over time. Extracting it programmatically is only possible for standard cases, e.g., when it is located in the default package.json file. Due to the great variety of JavaScript projects, this process can hardly be automated, as compared to other languages like Java, where project build systems are more homogeneous.

After a suitable bug is found, some preparatory steps are required before a bug can be added to BUGSJS. If necessary, irrelevant white space and comment modifications can be removed from the bug-fix patch, which is re-added to the repository as a new commit. Next, the production code
modifications should be separated from the test modifications by committing the changes separately on top of the buggy version. Then, the commits should be tagged according to the notation described in Section 3.6. Finally, the new bug can be submitted to BUGSJS using a GitHub pull request. The pull request has to contain the modified or added CSV files that contain the repository URL, the test runner command, and any additional commands (pre and post) if any. Adding precomputed data is not mandatory, but beneficial.

4. TAXONOMY OF BUGS IN BUGSJS

In this section, we present a detailed overview of the root causes behind the bugs in our benchmark. We adopted a systematic process to classify the nature of each bug, which we describe next.

4.1. Manual Labeling of Bugs

Each bug and associated information (i.e., bug report, and issue description) was manually analyzed by four authors (referred to as “taggers” hereafter) following an open coding procedure [46]. Four taggers specified a descriptive label to each bug assigned to them. The labeling task was performed independently, and the disagreements were discussed and resolved through dedicated meetings. Unclear cases were also discussed and resolved during such meetings.

First, we performed a pilot study, in which all taggers reviewed and labeled a sample of 10 bugs. Bugs for the pilot were selected randomly from all projects in BUGSJS. The consensus on the procedure and the final labels was high, therefore for the subsequent rounds the four taggers were split into two pairs, which were shuffled after each round of tagging.

The labels were collected in separate spreadsheets; the agreement on the final labels was found by discussion. During the tagging, the taggers could reuse existing labels previously created, should an existing label apply to the bug under analysis. This choice was meant to limit introducing nearly-similar labels for the same bug, and help taggers to use consistent naming conventions.

When inspecting the bugs, we looked at several sources of information, namely (1) the bug-fixing commit on the GitHub’s web interface containing the commit title, the description as well as at the code changes, and (2) the entire issue and pull-request discussions.

In order to achieve internal validation in the labeling task, we performed cross-validation. Specifically, we created an initial version of the taxonomy labeling around 80% of the bugs (353). Then, to validate the initial taxonomy, the remaining 20% (100) were simply assigned to the closest category in the initial taxonomy, or a new category was created, when appropriate. Bugs for the initial taxonomy were selected at random, but they were uniformly selected among all subjects, to avoid over-fitting the taxonomy towards a specific project. Analogously, the validation set was retained so as to make sure all projects were represented. Internal validation of the initial taxonomy is achieved if few or no more categories (i.e., labels) were needed for categorizing the validation bugs. The labeling process involved four rounds: first round (the pilot study) involved labeling 10 bugs, second round 43 bugs, and 150 bugs were analyzed in both third and fourth rounds.

4.2. Taxonomy Construction

After enumerating all causes of bugs in BUGSJS, we began the process of creating a taxonomy, following a systematic process. During a physical meeting, for each bug instance, all taggers reviewed the bugs and identified candidate equivalence classes to which descriptive labels were assigned. By following a bottom-up approach, we first clustered tags that correspond to similar notions into categories. Then, we created parent categories, in which that categories and their subcategories follow specialization relationship.

4.3. Taxonomy Internal Validation

We performed the validation phase in a physical meeting. Each of the four tagger classified independently one fourth of the validation set (25 bugs), assigning each of them to the most
appropriate category. After this task, all taggers reviewed and discussed the unclear cases to reach full consensus. All 100 validation bugs were assigned to existing categories, and no further categories were needed.

4.4. The Final Taxonomy

Figure 5. Taxonomy of bugs in the benchmark of JavaScript programs of BUGSJS.

Figure 5 presents a graphical view of our taxonomy of bugs in the JavaScript benchmark. Nodes represent classes and subclasses of bugs, and edges represent specialization relationships.
Specializations are not complete, disjoint relationships. Even though during labeling we tried assigning the most specific category, we found out during taxonomy creation that we had to group together many app-specific corner cases. Thus, some bugs pertaining to inner nodes were not further specialized to avoid creating an excessive number of leaf nodes with only a few corner cases.

At the highest level, we identified four distinct categories of causes of bugs, as follows:

1. Causes related to an **incomplete feature implementation**. These bugs are related either to an incomplete understanding of the main functionalities of the considered application, or a refinement in the requirements. In these cases, the functionalities have already been implemented by developers according to their best knowledge, but over time, users or other developers found out that they do not consider all aspects of the corresponding requirements. More precisely, given a requirement \( r \), the developer implemented a program feature \( f' \) which corresponds to only a subset \( r' \subset r \) of the intended functionality. Thus, the developer has to adapt the existing functionality \( f' \subset f \) to \( f \), in order to satisfy the requirement in \( r \). Typical instances of this bug category are related to one or more specific corner-cases that were unpredictable at the time in which that feature was initially created, or when the requirements for the main functionalities are changed or extended to some extent.

2. Causes related to an **incorrect feature implementation**. These bugs are also related to the mainstream functionalities of the application. Differently from the previous category, the bugs in this category are related to wrong implementation by the developers, for instance, due to an incorrect interpretation of the requirements. More precisely, suppose that given a requirement \( r \), the developer implemented a program feature \( f' \), to the best of her knowledge. Over time, other developers found out by the usage of the program, that the behavior of \( f' \) does not reflect the intended behavior described in \( r \), and opened a dedicated issue in the GitHub repository (and, eventually, a pull request with a first fix attempt).

3. Causes related to **generic** programming errors. Bugs belonging to this category are typically not related to an incomplete/incorrect understanding of the requirements by developers, but rather to common coding errors, which are also important from the point of view of a taxonomy of bugs.

4. Causes related to **perfective maintenance**. Perfective maintenance involves making functional enhancements to the program in addition to the activities to increase its performance even when the changes have not been suggested by bugs. These can include completely new requirements to the functionalities or improvements to other internal, or external quality attributes not affecting existing functionalities. When composing BUGSJS, we aimed at excluding such cases from the candidate bugs (see Section 3), however, the bugs that we classified in the taxonomy with this category were labeled as bugs by the original developers, so we decided to retain them in the benchmark.

We now discuss each of these categories in turn, in each case considering the subcategories beneath them.

1. **Incomplete feature implementation**

   This category contains 45% of the bugs overall, and has five subcategories, which we describe in the following subsection.

1.1. **Incomplete data processing**

   The bugs in this category are related to an incomplete implementation of a feature’s logic, i.e., the way in which the input is consumed and transformed into output.

   Overall, 27 bugs were found to be of this type. An example is Bug#7 of Hexo,* in which an HTML anchor was undefined, unless correct escaping of markdown characters is used.

---

*https://github.com/BugsJS/hexo/releases/tag/Bug-7-original
1.2 - Missing input validation

The bugs in this category are related to an incomplete input validation, i.e., the way in which the program checks whether a given input is valid, and can be processed further. Overall, 16% of the bugs were found to be of this type, and a further 16% in more specialized instances. This prevalence was mostly due to the nature of some of our programs. For instance, ESLint provides linting utilities for JavaScript code, and it is the most represented project in BUGSJS (73%). Therefore, being its main scope to actually validate code, we found many cases related to invalid inputs being unmanaged by the library, even though we found instances of these bugs also in other projects. For instance, in Bug#4 of Karma,† a file parsing operation should not be triggered on URLs having no line number. As such, in the bug-fixing commit, the proposed fix adds one more condition.

```javascript
- if (file && file.sourceMap) {
+ if (file && file.sourceMap && line) {
```

Another prevalent category is due to missing type check on inputs (11%), whereas less frequent categories were missing check of null inputs, empty parameters, and missing handling of spaces or other special characters (e.g., in URLs).

1.3 - Error handling

The bugs in this category are related to an incomplete handling of errors, i.e., the way in which the program manages erroneous cases, i.e., exception handling. Overall, 3% of the bugs were found to be of this type. For instance, in Bug#14 of Karma,‡ the program does not throw an error when using a plugin for a browser that is not installed, which is a corner-case missed in the initial implementation. Additionally, we found two cases specific to callbacks.

1.4 - Incomplete configuration processing

The bugs in this category are related to an incomplete configuration, i.e., the values of parameters accepted by the program. Overall, 2% of the bugs were found to be of this type. For instance, in Bug#10 of ESLint.§ an invalid configuration is used when applying extensions to the default configuration object. The bug fix updates the default configuration object’s constructor to use the correct context, and to make sure the config cache exists when the default configuration is evaluated.

1.5 - Incomplete output message

The last sub-category pertains to bugs related to incomplete output messages by the program. Only three bugs were found to be of this type. For instance, in Bug#8 of Hessian.js¶ the program casts the values exceeding `Number.MAX_SAFE_INTEGER` as string, to allow safe readings of large floating point values.

2 - Incorrect feature implementation

This category contains 48% of the bugs overall, and has seven subcategories, which we describe in the following subsections.

---

† [https://github.com/BugsJS/karma/releases/tag/Bug-4-original](https://github.com/BugsJS/karma/releases/tag/Bug-4-original)
‡ [https://github.com/BugsJS/karma/releases/tag/Bug-14-original](https://github.com/BugsJS/karma/releases/tag/Bug-14-original)
§ [https://github.com/BugsJS/eslint/releases/tag/Bug-10-original](https://github.com/BugsJS/eslint/releases/tag/Bug-10-original)
¶ [https://github.com/BugsJS/hessian.js/releases/tag/Bug-8-original](https://github.com/BugsJS/hessian.js/releases/tag/Bug-8-original)
2.1 - Incorrect data processing

The bugs in this category are related to a wrong implementation of a feature’s logic, i.e., the way in which the input is consumed and transformed into output.

Overall, 75 bugs were found to be of this type, with two subcategories due to a wrong type comparison (1 bug), or an incorrect initialization (10 bugs). An example of this latter category is Bug#238 of ESLint,† in which developers remove the default parser from CLIEngine options to fix a parsing error.

- parser: DEFAULT_PARSER
+ parser: ""

2.2 - Incorrect input validation

The bugs in this category are related to a wrong input validation, i.e., the way in which the program checks whether a given input is valid, and can be processed further.

Overall, 19% of the bugs were found to be of this type, with three subcategories due to unnecessary type checks (7 bugs), incorrect handling of special characters (16 bugs), or empty input parameters given to the program (2 bugs). As an example of this latter category, in Bug#171 of ESLint,** the arrow-spacing rule did not check for all spaces between the arrow character (=>) within a given code. Therefore, it is updated as follows:

- while (t.type !== "Punctuator" || t.value !== "=>") {
  + while (arrow.value !== "=>") {

2.3 - Incorrect filepath

The bugs in this category are related to wrong paths to external resources necessary to the program, such as files. For instance, in Bug#6 of ESLint,†† developers failed to check for configuration files within sub-directories. Therefore, the code was updated as follows:

- if (!directory)
  + if (directory) directory = path.resolve(this.cwd, directory);

2.4 - Incorrect output

The bugs in this category are related to incorrect output by the program. For instance, in Bug#7 of Karma,* the exit code is wrongly replaced by null characters (\0x00), which results in squares (□□□□□□□□□□) being displayed in the standard output.

- return exitCode
  + return {exitCode: exitCode, buffer: buffer.slice(0, tailPos)}

2.5 - Incorrect configuration processing

The bugs in this category are related to an incorrect configuration of the program, i.e., the values of parameters accepted.

Nine bugs were found to be of this type. For instance, in Bug#145 of ESLint,† a regression was accidentally introduced where parsers would get passed additional unwanted default options even when the user did not specify them. The fix updates the default parser options to prevent any unexpected options from getting passed to parsers.

- let parserOptions = Object.assign({}, defaultConfig.parserOptions);
  + let parserOptions = {};

†https://github.com/BugsJS/eslint/releases/tag/Bug-238-original
**https://github.com/BugsJS/eslint/releases/tag/Bug-171-original
††https://github.com/BugsJS/eslint/releases/tag/Bug-6-original
*https://github.com/BugsJS/karma/releases/tag/Bug-7-original
†https://github.com/BugsJS/eslint/releases/tag/Bug-145-original
2.6 - Incorrect handling of regex expressions

The bugs in this category are related to an incorrect use of regular expressions. Seven bugs were found to be of this type. For instance, in Bug#244 of ESLint, a regular expression is wrongly used to check that the function name starts with setTimeout.

2.7 - Performance

The bugs in this category caused the program to use an excessive amount of resources (e.g., memory). Only four bugs were found to be of this type. For instance, in Bug#85 of ESLint, a regular expression susceptible to catastrophic backtracking was used. The match takes quadratic time in the length of the last line of the file, causing Node.js to hang when the last line of the file contains more than 30,000 characters. Another representative example is Bug#1 of Node-Redis in which parsing big JSON files takes substantial time due to an inefficient caching mechanism which makes the parsing time grow exponentially with the size of file.

3 - Generic

This category contains 6% of the bugs overall, and has six subcategories, which we describe next.

3.1 - Typo This category refers to typographical errors by the developers.

We found three such bugs in our benchmark. For instance, in Bug#321 of ESLint, a rule is intended to compare the start line of a statement with the end line of the previous token. Due to a typo, it was comparing the end line of the statement instead, which caused false positives for multiline statements.

3.2 - Return statement The bugs in this category are related to either missing return statements (3 bugs), or incorrect usage of return statements (1 bug). For instance, in Bug#8 of Mongoose, the fix involves adding an explicit return statement.

- `this.constructor.update.apply(this.constructor, args);`
+ `return this.constructor.update.apply(this.constructor, args);`

3.3 - Variable initialization The bugs in this category are related to either missing initialization of variables statements (8 bugs), or to an incorrect initialization of variables (4 bugs). For instance, in Bug#9 of Express, the fix involves correcting a wrongly initialized variable.

- `mount_app.mountpath = path;`
+ `mount_app.mountpath = mount_path;`

3.4 - Data processing The bugs in this category are related to incorrect processing of information.

Six bugs were found to be of this type. For instance, in Bug#184 of ESLint, developers fixed the possibility of passing negative values to the string.slice function.

- `currentText.slice(node.range[0] - (beforeCount || 0))`
  + `currentText.slice(Math.max(node.range[0] - (beforeCount || 0), 0))`

---

∗[https://github.com/BugsJS/express/releases/tag/Bug-5-original](https://github.com/BugsJS/express/releases/tag/Bug-5-original)
†[https://github.com/BugsJS/eslint/releases/tag/Bug-184-original](https://github.com/BugsJS/eslint/releases/tag/Bug-184-original)

3.5 - Missing type conversion The bugs in this category are related to missing type conversions. Three bugs were found to be of this type. For instance, in Bug#4 of Shields, developers forgot to convert labels to string prior to apply the uppercase transformation.

```javascript
- data.text[0] = data.text[0].toUpperCase();
+ data.text[0] = ('' + data.text[0]).toUpperCase();
```

3.6 - Loop statement We found only one bug of this type—Bug#304 of Shields,—related to an incorrect usage of loop statements.

```javascript
- while ((currentAncestor = currentAncestor.parent))
-   if (isConditionalTestExpression(currentAncestor)) {
-     return currentAncestor.parent;
-   }
- }
+ do {
+   if (isConditionalTestExpression(currentAncestor)) {
+     return currentAncestor.parent;
+   }
+ } while ((currentAncestor = currentAncestor.parent));
```

4 - Perfective maintenance

This category contains only 1% of the bugs. For instance, in Bug#209 of ESLint, developers fix JUnit parsing errors which treat no test cases having empty output message as a failure.

5. ANALYSIS OF BUG-FIXES

To gain a better understanding about the characteristics of bug-fixes of bugs included in BUGSJS, we have performed two analyses to quantitatively and qualitatively assess the representativeness of our benchmark. This serves as an addition to the taxonomy presented in Section 4.4 which, by connecting the bug types to the bug-fix types, can support applications such as automated fault localization and automated bug repair.

5.1. Code Churn

Code churn is a measure that approximates the rate at which code evolves. It is defined as the sum of the number of lines added and removed in a source code change. The churn is an important measure with several uses in software engineering studies, e.g., as a direct or indirect predictor in bug prediction models [47, 48].

We utilize the distribution of code churn to describe the overall data distribution in the benchmark, and understand to what extent it can be used to support software testing techniques (e.g., fault localization, program repair) that are directly affected by the size of the source code changes.

Figure 6 illustrates the distribution of code churn in each bug-fixing commit in BUGSJS, before cleaning the patches (Figure 6a), after removing changes unrelated to the fix, while retaining related comments added or removed during the bug fix (Figure 6b), and after cleaning the fixes and also removing all the comments and whitespaces (Figure 6c). The box and whisker plots show the quartiles of the data, enhanced by the underlying violin plots to better depict the data distribution.

The median value for the code churn required to fix a bug is 5 and 17 for production and test code, respectively (excluding irrelevant changes, comments, and whitespaces). This essentially means that for each line of bug-fixing change in the production code, more than three lines of test code were changed on average.

---

‡https://github.com/BugsJS/shields/releases/tag/Bug-4-original
§https://github.com/BugsJS/eslint/releases/tag/Bug-304-original
¶https://github.com/BugsJS/eslint/releases/tag/Bug-209-original
We can also observe that nearly half of the changes done to the production code involve more than five lines of code, suggesting that existing fault localization and repair techniques will fall short in being applicable on real JavaScript bugs, as they currently deal with one-liner changes only. Previous work showed that the same conclusion holds for Java projects [49].

In addition, comparing the median values in Figure 6 suggests that developers, on average, add/remove one line of unrelated code changes (i.e., $8 - 7$) and two lines of comments/whitespace (i.e., $7 - 5$) when fixing a bug. This essentially shows the importance of the manual isolation and cleaning performed on the bugs included in BUGSJS.

The largest value for churn in test code is 3,632 lines (Figure 6c), occurring in a bug-fixing commit in the ESLint project. This commit corresponds to generated test data committed along with the production code bug-fixing changes. A closer look at the data revealed that there are five other such commits in this project, all changing more than 1,000 lines of test code. Such commits in which the number of changes is exceptionally high (i.e., outliers) should be carefully handled or discarded when conducting empirical studies.

5.2. Patterns in Bug Fixes

We further analyzed the bugs in BUGSJS to observe occurrence of low-level bug fixes for recurring patterns. Previous work [45, 49, 50] have studied patterns in bug-fixing changes within Java programs. They suggest that the existence of patterns in fixes reveals that specific kinds of code constructs (e.g., if conditionals) could signal weak points in the source code where developers are consistently more prone to introduce bugs [45].

Methodology. Four authors of this paper manually investigated all 453 bug-fixing commits in BUGSJS and attempted to assign the bug-fixing changes to one of the predefined categories suggested in previous studies. In particular, we used the categories proposed by Pan et al. [45]. These categories, however, are related to Java bug fixes. Our aim is to assess whether they generalize to JavaScript, or whether, in contrast, JavaScript-specific bug fix patterns would emerge.

Following the original category definitions [45], we assigned each individual bug-fix to exactly one category. Disagreements concerning classification or potential new categories were resolved by further discussion between the authors. To identify the occurrences of such patterns, we opted for a manual analysis to ensure covering potential new patterns, and to add an extra layer of validation against potential misclassifications (e.g., false positives).

Table V shows the number of bug fix occurrences followed the categories by Pan et al. [45]. (For fixes spanning multiple lines, we possibly assigned more than one category to a single bug-fixing commit, hence, the overall number of occurrences is greater than the number of bugs.)

Note that, since the categories proposed by Pan et al. have been derived from Java programs, we had to make sure to match them correctly on JavaScript code. In particular, until ECMAScript 2015, JavaScript did not include syntactical support for classes. Classes were emulated using functions as constructors, and methods/fields are added to their prototype [51, 52, 53]. In addition, object

</table>

 literals could represent imaginary classes: comma-separated list of name-value pairs enclosed in curly braces, where the name-value pairs declare the class fields/methods. We have taken all these aspects into account during the assignment task, to avoid misclassifications.

Our analysis revealed that, in 88% of bugs in BUGSJS, the fix includes changes falling into one of the proposed categories. The most prevalent bug fix patterns involve changing an if statement (i.e., modifying the if condition or adding a precondition), changing assignment statements, and modifying function call arguments (Table V). The same three categories have been also found to be most recurring in Java code, but with a different ordering: Pan et al. [45] report that the most prevalent fix patterns are changes done on method calls, if conditions, and assignment expressions.

In addition, we found that changes to class fields are also prevalent. This can be explained by the fact that in JavaScript, object literals are frequently created without the need for defining a class or function constructor, and, as far as fixing bugs is concerned, updating their attributes (i.e., fields) is a common practice.

5.2.1. JavaScript-related Bug-Fixing Patterns We found three new recurring patterns in our benchmark, which we describe next.

**Changes to the return statement’s expression.** We found a recurring bug-fixing pattern involving changing the return statement’s expression of a function, i.e.:

```javascript
- return node.type !== "A";
+ return !(node.type === "A" && lastI.type === "R");
```

**Variable declaration.** In JavaScript, it is possible to use a variable without declaring it. However, this has implications which might lead to subtle silent bugs. For example, when a variable is used inside a function without being declared, it is “hoisted” to the top of the global scope. As a consequence, it is visible to all functions, *outside its original lexical scope*, which can lead to name clashes. This fix pattern essentially includes declaring a variable which has already been in use.

**Initialization of empty variables.** This bug-fixing pattern category corresponds to Hanam et al.’s [25] first bug pattern, i.e., Dereferenced non-values. To avoid this type of bug, developers can add additional if statements, comparing values against “falsey” values (“undefined” type, or “null”). This bug fix pattern provides a shortcut to using an if statement, by using a logical “or” operator, e.g., `a = a || {}`, which means that the value of `a` will remain intact if it already has a “non-falsey” value, or it will be initialized with an empty object otherwise.
5.3. Bug Taxonomy and Bug-Fixing Types

We compared the taxonomy with the bug-fixing patterns used to fix the bugs. Figure 7, Figure 8 and Figure 9 present Sankey diagrams showing the relationship of the assigned bug categories with the bug-fixing patterns of Pan et al. [45] and the JavaScript-related bug-fixing patterns described in Section 5.3. We focused our analysis on the first three main bug categories of our taxonomy. For presentational clarity, each figure shows a diagram for one of such main categories. The left side of the diagrams shows one of the main bug categories, unfolded into its sub-categories. The right side depicts the associated bug-fixing patterns. The None node indicates that no patterns were applicable. In the middle, each bug category is connected to each bug-fixing patterns that are used to fix the bugs belonging to the bug category. The thickness of the curved lines between the nodes indicates the cardinality of the association.

For example, in Figure 7, the node incomplete feature implementation is connected to the sub-category missing input validation with a thick line, due to the majority of the bugs in this main category belonging to that sub-category. Then, the node of that sub-category is connected to the node of the IF-CC bug-fixing pattern with a relatively thick line, because a considerable amount of bugs fixes are classified into that category. The nodes of the bug categories can be wider than the total width of the lines connected from the right side, because bug fixes can be assigned with multiple bug patterns, whereas each bug is assigned with exactly one bug category. Also, there are bugs that are only assigned to a main category, e.g., Missing input validation, but not to any sub-category, which resulted in the direct lines between pattern and main category nodes.

Table VI gives a description about the bug-fixing pattern abbreviations. We now discuss each of the bug categories in detail.

5.3.1. Incomplete feature implementation Figure 7 illustrates the connection between the bugs under the Incomplete feature implementation category and the related bug-fixing patterns.

Missing input validation. Table VII shows that the majority of the bugs assigned with this category are fixed by if-related (53), assignment related (29) and method declaration related (22) changes. The most common are changing a condition in an if statement (IF-CC), changing an assignment expression (AS-CE) or by adding a method declaration (MD-ADD). The most numerous sub-category is the Missing type check and the related bugs are mainly fixed by if-related changes (39), the top two are IF-CC and IF-APCJ and by changing an assignment expression (18 AS-CE). The fixes of bugs in the Missing handling of special characters sub-category often contain changes in an assignment expression (6 AS-CE) and in an if statement (5), mainly adding post-condition checks (IF-APTC). Bugs belonging to the Missing null check and the Empty input parameters sub-categories are mainly fixed by changing an if condition (5). The Missing handling of spaces sub-category is connected to various bug-fixing patterns and none of them is dominant.

Incomplete configuration processing. The majority of the bug fixes of this category contain if-related patterns (9), mainly IF-APC, adding a precondition check. The Missing type check sub-category of Incomplete configuration processing is too small to draw meaningful conclusions.

Error handling. Bugs of this category are typically fixed with if-related fixes (12), namely IF-APCJ, IF-APC and IF-CC. The second most common fix patterns are MC-DNP, changing the number of parameters (3) and MD-ADD, adding a method declaration (4). The Callbacks sub-category of Error handling is related to a variety of bug-fixing patterns (4 if-related, 1 assignment related, 1 method call related and 1 sequence related).

Incomplete output message. Bugs assigned with this category are usually fixed by changing the parameters of function calls (2 MC-DAP, 1 MC-DNP).

Incomplete data processing. Bugs belonging to this category were fixed in a variety of ways. The most common pattern are method call related (11), but there is no dominant bug-fixing pattern.

5.3.2. Incorrect feature implementation Figure 8 illustrates the connection between the bugs under the Incorrect feature implementation category and the related bug-fixing patterns.

</table>

Incorrect input validation. The most dominant bug-fixing patterns of this category are if-related (56), method call related (27) and assignment related (25). The most numerous if-related pattern is IF-CC and the most numerous method call related pattern is MC-DAP. Furthermore, return statement related (12 JS-Return) and method declaration related (10 MD-ADD and 5 MD-CHG) patterns are also quite common. In the Unnecessary type check sub-category the most common pattern is if-related (6 IF-CC and 1 IF-RMV) and the second most common pattern is the assignment related pattern (5 AS-CE). Bugs belonging to the biggest input validation related sub-category, the Incorrect handling of special characters, are usually fixed with method call related changes (10 MC-DAP and 2 MC-DM), with assignment related changes (9 AS-CE) and with method declaration related changes (9 MD-ADD and 1 MD-RMV). The Empty input parameters sub-category of Incorrect input validation is too small to draw meaningful conclusions.
Incorrect data processing. Similarly to the Incomplete data processing category, bugs belonging to this category were fixed in a variety of ways. There is no dominant bug-fixing pattern. The most numerous patterns are if-related (39), method call related (27) and assignment related (24). The Incorrect initialization sub-category is interestingly not connected to if-related patterns at all. The bug fixes of this category are connected to only assignment related (5), sequence related (5) and method call related (4) patterns. The Incorrect type comparison sub-category of Incorrect data processing is too small to draw meaningful conclusions.
Incorrect handling of regex expressions. Bugs assigned to this category are mostly fixed with assignment related (13 AS-CE) and method call related (6 MC-DAP) changes.

Incorrect filepath. Here, the most dominant bug-fixing patterns are assignment related (4), method call related (4) and if-related (4). The variety of connected patterns is large.

Incorrect output. Bugs of this category are usually fixed by changing method calls (3MC-DM and 2 MC-DAP) and by changing return statements (3 JS-Return). The Incorrect output message subcategory contains bugs with fixes that mostly involve changes to the parameters of method calls.
(9 MC-DAP and 1 MC-DNP) and changes to condition expressions in if statements (5 IF-CC, 2 IF-RMV and 1 IF-APCJ).

**Incorrect configuration processing.** The most dominant bug-fixing pattern for this category is assignment related (5 AS-CE), but a variety of other patterns occur as well (3 if-related, 2 method call related, 1 JavaScript related, 1 loop related and 1 method declaration related).

**Performance.** The majority of the bug-fixing patterns used for fixing bugs of this category is SQ-AFO, adding operations in an operation sequence of field settings (7). The second most common patterns are if-related (5 IF-APC and 1 IF-APCJ).

![Diagram of bug-fixing patterns used in the Generic category](image)

5.3.3. **Generic** Figure 9 illustrates the connection between the bugs under the Generic category and the related bug-fixing patterns.

**Variable initialization.** The bug fixes of the Missing variable initialization sub-category contain five types of bug-fixing patterns. The most dominants are the JavaScript related patterns (2 JS-Return, 2 JS-Initialization and 1 JS-Declaration) and the class field related patterns (2 CF-CHG and 2 CF-ADD). In the other sub-category, Incorrect variable initialization, changing an assignment expression (3 AS-CE) is the most dominant.

**Data processing.** Similarly to the other two cases of data processing bugs, the associated bug fixes contain a variety of patterns (2 JavaScript related, 2 method call related, 1 if-related, 1 assignment related and 1 sequence related) and there is no dominant bug-fixing pattern.
Missing type conversion. The bug fixes of this category mostly involve changes in an assignment expression (2 AS-CE), but adding a precondition check to an if statement (1 IF-APC) and removing an operation from an operation sequence of method calls (1 SQ-RMO) also appears.

Typo. For this category, there is no dominant bug-fixing pattern (2 if-related, 2 method call related, 1 assignment related, and 1 method declaration related) which essentially means typos can occur at any place in the code.

Return statement. This category contains too few bug-fixing patterns to draw meaningful conclusions. Surprisingly, the bug fixes do not fall into the JS-Return category.

Loop statement. There is only one bug in this category and its fix does not contain any bug-fixing patterns, therefore we cannot draw meaningful conclusions here.

5.3.4. Highlights Table VII provides statistics about the occurrences of each bug-fix type corresponding to the bug types. The table can serve to analyze the emergence of correlations between bug-fix types and bug types. Overall, the most common bug-fixes types are if-related (291), the second most common are assignment related (166), and the third most common are method call related (152) bug-fixes. These bug-fixes types are mostly related to the most prominent bug categories, namely missing input validation, incorrect input validation, and incorrect data processing. Another correlation is that assignment related fixes are also the preferred way to fix regexes. These are perhaps the only correlations between bug-fix types and bug types that are observable in our benchmark.

6. DISCUSSION

Our results might drive devising novel software analysis and repair techniques for JavaScript, with BUGSJS being a suitable real-world bug benchmark for their evaluation, as well as inform developers of the most error-prone constructs.

In the rest of this section, we discuss some of the potential uses of our taxonomy, together with possible use cases of our benchmark in supporting empirical studies in software analysis and testing, as well as its limitations and threats to validity of our study.

6.1. Directing Research Efforts

Our taxonomy and associated data can be useful in several contexts related to JavaScript analysis and testing contexts. Our study reveals that the majority of bugs are related to mistakes by the developers. This finding is in line with those of the previous study by Ocariza et al. [5] on client-side JavaScript programs. Overall the bug fixes included in BUGSJS cover a diverse range of categories, some of which being specific only to JavaScript (Section 5.3). For instance, Incorrect/missing input validation and Incorrect/incomplete data processing caused the majority of bugs we observed, 50% and 23%, respectively. It has to be said that this prevalence is due to the ESLint project, which is a linting tool, essentially a code validator. While ESLint may be not representative of the majority of JavaScript web services, it is a very popular JavaScript linting tool, being recommended by multiple comparative studies above other tools like JSLint, JSHint and JSCS. Moreover, ESLint is supported by JetBrains in the WebStorm IDE and by Vue.js to validate their templates, and by Facebook’s React to help enforce their coding rules. This adoption suggests that major companies recognize input validation/data processing tasks as vital throughout the software development.

Another relevant source of bugs is due to missing type checks, a construct which is particularly problematic due to the dynamically-typed nature of JavaScript, which makes it easier for developers

Researchers have proposed approaches for addressing this class of errors and finding ways to prevent them [1, 9, 54, 55, 56, 57], which suggests that this class of errors deserves considerable attention.

6.1.1. Benchmark for Testing Techniques Various fields of testing research can benefit from BUGSJS. First, our benchmark includes more than 25k JavaScript test cases, which makes it a rather large dataset for different regression testing studies (e.g., test prioritization, test minimization, or test selection). Second, BUGSJS can play a role to support research in software oracles (e.g., automated generation of semantically-meaningful assertions), as it contains all test suites’ evolution as well as examples of real fixes made by developers. Additionally, these can be used to drive the design of automated test repair techniques [58, 59]. Finally, test generation or mutation techniques for JavaScript can be evaluated on BUGSJS at a low cost, since pre-computed coverage information are available for use.
6.1.2. **Bug prediction using static source code analysis** To construct reliable bug prediction models, training feature sets are extracted from the source code, comprising instances of buggy and healthy code, and static metrics. BUGSJS can support these studies since it streamlines the hardest part of constructing the training and testing datasets, that is, determining whether a given code element is affected by a bug. As such, the cleaned fixes included in BUGSJS make this task much easier. Also, the availability of both uncleaned and cleaned bug-fixing patches in the dataset can allow assessing the sensitivity of the proposed models to the noise. In addition, some of the most important static code metrics are readily available as precomputed data.

6.1.3. **Bug localization** BUGSJS can support devising novel bug localization techniques for JavaScript. Approaches that use NLP can take advantage of our benchmark since bugs are readily available to be processed. Indeed, text retrieval techniques are used to formulate a natural language query that describes the observed bug. To this aim, BUGSJS contains pointers to the natural language bug description and discussions for several hundreds of real world bugs. Similarly, BUGSJS will be of great benefit for other popular bug localization approaches, *e.g.*, the spectrum-based techniques [60, 61, 62, 63] because all the necessary data—test case outcomes, code coverage and bug information—are readily available.

6.1.4. **Automated program repair** Automated program repair techniques aim at automatically fixing bugs in programs, by generating a large pool of candidate fixes, to be later validated. The manually cleaned patches available in BUGSJS can be used as learning examples for patch generation in novel automated program repair for JavaScript. Also, BUGSJS provides an out-of-the-box solution for automatic dynamic patch validation. Detailed classification of the bugs according to our bug-taxonomy and the bug-fix types provides to this kind of research additional useful information.

6.2. **Directing Developer Efforts**

6.2.1. **Improving Manual Repair Processes** In the absence of automated program repair techniques, knowledge about the causes of bugs could help developers manually fix programs, both by increasing their awareness to bugs causes, and helping them prioritize the inspection of possible causes based on the relative importance of such causes in our taxonomy.

6.2.2. **Avoiding Bugs** Bugs avoidance pertain to cases in which programmers are provided with information to assist them in avoiding bugs, and it is up to them to choose what information to utilize and how. One way to promote bugs avoidance involves educating developers and maintainers of JavaScript applications as to the causes and probabilities of bugs. Such education could be supported by information present in our taxonomy and the data that underlie it. First, consider code changes activities. We observed that many of the bugs involving missing type checks resulted from simple code changes, i.e., missing an IF-condition in a statement. Second, consider code creation tasks. When creating new code, programmers can enforce the practice of adding input validation as a must-do of their daily activities. Finally, consider test case creation. Testers can use our taxonomy to focus their test case creation to avoid the most bug-prone categories.

6.2.3. **Preventing Bugs** Bugs prevention, in contrast to bugs avoidance, involves the use of automated approaches for ensuring that bugs do not occur, even though humans might be included in the feedback loop. For example, programmers may take advantage of tools like checkers and linting tools that enable static and dynamic analysis automatically [64], and our taxonomy could help improve on certain constructs that are particularly challenging for developers.

6.2.4. **IDE Enhancements** Another class of bugs prevention approaches involves improvements in web programming and testing IDEs. Analysis techniques that operate concurrently with program development and maintenance may be quite effective, and such techniques could also be guided by our taxonomy. Modern IDEs for code development typically employ such approaches: as programmers edit, they point out problems or provide useful information based on the programmers’
actions. JavaScript application development IDEs employ such approaches also, but to our knowledge, no such IDEs also build in assistance related to testing efforts. Such IDEs could aid in bugs avoidance by alerting developers to possible effects or bad practices and letting them choose whether or not to act on them. They could aid in prevention by prohibiting certain actions or by recommending the creation of constructs. Let us take as example the return statement related issues. Our taxonomy highlighted that developers often fix bugs by changing the return statement. Thus, IDEs can be improved with new data flow testing techniques that check that JavaScript objects’ states are preserved during the execution before they are returned, or that inform a change-impact analysis technique to show how the change to an object affects the final output.

6.3. Limitations

BUGSJS includes only server-side JavaScript applications developed with the Node.js framework. As such, experiments evaluating the client-side (e.g., the DOM) are not currently supported. While our survey revealed a large number of subjects being used for evaluating such techniques, the majority of these programs could not be directly included in our proposed benchmark.

Indeed, in the JavaScript realm, the availability of many implementations, standards, and testing frameworks poses major technical challenges with respect to devising a uniform and cohesive bugs infrastructure. Similar reasoning holds for selecting Mocha as a reference testing framework. Running tests for browser-based programs may require complex and time-consuming configurations. When dealing with a large and diverse set of applications, achieving isolation would require automating each single configuration for all possible JavaScript development and testing frameworks, which is a cumbersome task. Clearly, this is a potential limitation and bias for experiments that use BUGSJS, and we are considering for a future revision of the benchmark to support other environments as well. We must note, however, that due to the mentioned specialities of the JavaScript ecosystem, we do not expect to be able to fully cover the plethora of the different execution environments. Nevertheless, all the subjects included in BUGSJS have been previously used by at least one work in our literature survey (e.g., BOWER, SHIELDS, KARMA, NODE-REDIS, and MONGOOSE are all used in bug-related studies).

6.4. Threats to Validity

The main threat to the internal validity of this work is the possibility of introducing bias when selecting and classifying the surveyed papers and the bugs included in the benchmark.

Our paper selection was driven by the keywords related to software analysis and testing for JavaScript (Section 2). We may have missed relevant studies that are not captured by our list of terms. We mitigate this threat by performing an issue-by-issue, manual search in the major software engineering conference proceedings and journals, followed by a snowballing process. We, however, cannot claim that our survey captures all relevant literature; yet, we are confident that the included papers cover the major related studies.

Concerning the bugs, we manually classified all candidate bugs into different categories (Section 3.3), and the retained bugs into categories pertaining to existing bug and fix taxonomies (Section 5.2). To minimize classification errors, multiple authors simultaneously analyzed the source code and performed the classifications individually, and disagreements were resolved by further discussions among the authors. Concerning the bug’s classification for taxonomy construction, the first four authors classified the bugs manually. This task, however, requires reasoning that cannot be automated, so it is difficult to envision less threat-prone approaches. To reduce the subjectivity involved in the task, the authors followed a systematic and structured procedure, with multiple interactions.

Threats to the external validity concern the generalization of our findings. We, by no means, claim that our benchmark represents all relevant web apps. We selected only 10 applications and our bugs may not generalize to different projects. Also, other relevant classes of bugs might be unrepresented or underrepresented within our benchmark, which is to date quite overfitted towards ESLint, i.e., the most represented project. Nevertheless, we tried to mitigate this threat by selecting applications with different sizes and pertaining to different domains. We hope that our framework will provide
an entry point and a reference for future improvements as other subject systems are necessary to fully confirm the generalizability of our results, and corroborate our findings.

Another generalization threat concerns our taxonomy. Taxonomies are conceptual maps derived from empirical observations; as such they typically evolve as additional observations of the world are made. We expect the same to be true of our taxonomy, and thus, it is not necessarily the case that any attempt to apply the taxonomy to subsequent programs will allow every type of bug in those applications to be categorized. In such cases the taxonomy will require adjustments. This work attempts to reduce this threat by applying a validation phase to our initial taxonomy.

With respect to reproducibility of our results, all classifications, subjects, and experimental data are available online, making the analysis reproducible.

7. RELATED WORK

7.1. Benchmarks

7.1.1. C, C++, and C# Benchmarks The Siemens benchmark suite [65] was one of the first datasets of bugs used in testing research. It consists of seven C programs, containing manually seeded faults. The first widely used benchmark of real bugs and fixes is the SIR (Software-artifact Infrastructure Repository) [14], which includes the Siemens benchmark, and extends it with nine additional large C programs and seven Java programs. SIR also features test suites, bug data, and automation scripts. The benchmark contains both real and seeded faults, the latter being more frequent.

Le Goues et al. [16] proposed two benchmarks for C programs called ManyBugs and IntroClass, which include 1,183 bugs in total. The benchmarks are designed to support the comparative evaluation of automatic repair, targeting large-scale production (ManyBugs) as well as smaller (IntroClass) programs. ManyBugs is based on nine open-source programs (5.9M LOC and over 10k test cases) and it contains 185 bugs. IntroClass includes 6 small programs and 998 bugs.

Rahman et al. [66] examined the OpenCV project mining 40 bugs from seven out of 52 C++ modules into the benchmark Pairika. The seven modules analyzed contain more than 490k LOC, about 11k test cases and each bug is accompanied by at least one failing test.

Lu et al. [67] propose BugBench, a collection of 17 open-source C/C++ programs containing 19 bugs pertaining to memory and concurrency issues.

Codeflaws [68] contains nearly 4k bugs in C programs, for which annotated ASTs with annotated syntactic differences between buggy and patch code are provided.

7.1.2. Java Benchmarks Just et al. [15] presented Defects4J, a bug database and extensible framework containing 357 validated bugs from five real-world Java programs. BUGSJS shares with Defects4J the idea of mining bugs from the version control history. However, BUGSJS has some additional features: subject systems are accessible in the form of git forks on a central GitHub repository, which maintains the whole project history. Further, all programs are equipped with pre-built environments in form of Docker containers. Moreover, in this paper we also provide a more detailed analysis of subjects, tests, and bugs.

Bugs.jar [69] is a large-scale dataset intended for research in automated debugging, patching, and testing of Java programs. Bugs.jar consists of 1,158 bugs and patches, collected from eight large, popular open-source Java projects.

iBugs [70] is another benchmark containing real Java bugs from bug-tracking systems originally proposed for bug localization research. It is composed of 390 bugs and 197k LOC coming from three open source projects.

7.1.3. Multi-language Benchmarks QuixBugs [18] is a benchmark suite of 40 confirmed bugs used in program repair experiments targeting Python and Java with passing and failing test cases.

† the total number of bugs is 1,623, of which 998 are those in common between two test suites.
‡ this is reported in the original publication; the newer versions of the benchmark include additional bugs.
§ created by independent authors [44].
* only the number of faulty program versions is reported.

`BugSwarm` [17] is a recent dataset of real software bugs and bug fixes to support various testing empirical experiments such as test generation, mutation testing, and fault localization.

`Code4Bench` [71] is another cross-language benchmark comprising C/C++, Java, Python, and Kotlin programs among others. Code4Bench also features a coarse-grained bug classification based on an automatic fault localization process for which faults were classified only in three groups, namely addition, modifications, and deletion. In contrast, `BUGSJS` focuses on JavaScript bugs, for which we provide a fine-grained analysis based on a rigorous manual process.

7.1.4. Benchmarks Comparison

We summarize the related benchmarks and compare their main features to `BUGSJS` in Table VIII. The table includes the language(s) in which the programs were written and the kind of bugs the benchmarks contain. Further, the table indicates whether the modified versions have been cleaned from irrelevant changes, e.g., achieving the isolation property, whether the benchmark includes quantitative or qualitative analyses of the faults. These information were retrieved in the papers in which the benchmarks were proposed first.

The table highlights that `BUGSJS` is the only benchmark that contains JavaScript programs. This paper also provides both a quantitative analysis of the benchmark, and a qualitative analysis of the bugs (from which a taxonomy was derived) and the bug fixes (by comparing them with existing taxonomies). For instance, in the case of Defect4J, the original paper proposed only the benchmark [15], whereas a quantitative analysis was added in a subsequent paper by Sobreira et al. [44]. More qualitative analyses were also made by Sobreira et al. [44] and Motwani et al. [72], who independently propose two orthogonal classification of repairs.

To summarize, `BUGSJS` is the first benchmark of bugs and related artifacts (e.g., source code and test cases) that targets the JavaScript domain. In addition, `BUGSJS` differentiates from the previously-mentioned benchmarks in the following aspects: (1) the subjects are provided as `git` forks with complete histories, (2) a framework is provided with several features enabling convenient usage of the benchmark, (3) the subjects and the framework itself are available as GitHub repositories, (4) Docker container images are provided for easier usage, (5) the bug descriptions are accompanied by their natural language discussions, as well as (6) a manually-derived bug taxonomy and a comparison with an existing bug-fixes taxonomy.

7.2. Bug Taxonomies

There are several industry standards for categorizing software bugs, such as the IEEE Standard Classification for Software Anomalies [73], or IBM’s Orthogonal Defect Classification [74]. However, these are either too generic or more process-related, and are not suitable for categorizing...
bugs in BUGSJS. Also, there are countless categorization schemes proposed by various testing and defect management tool and service vendors, which are also less relevant for our research.

Hanam et al. [25] discuss 13 cross-project bug patterns occurring in JavaScript pertaining to six categories, which are the following: Dereferenced non-values (e.g., Uninitialized variables), Incorrect API config (e.g., Missing API call configuration values), Incorrect comparison (e.g., \( \text{===} \) and \( \text{==} \) used interchangeably), Unhandled exceptions (e.g., Missing try-catch block), Missing arguments (e.g., Function call with missing arguments), and Incorrect this bounding (e.g., Accessing a wrong this reference).

Since this is probably the closest related work to our taxonomy presented in Section 4.4, we tried to assign all 453 bugs of BUGSJS to one of these categories as well. Our analysis found 42 occurrences of the categories proposed by Hanam et al., most of them (35) belonging to Dereferenced non-values. This shows that these patterns do exist in the bugs that we have in BUGSJS, but they only cover a small subset of them. The majority of the rest of the bugs are indeed logical errors made by developers during the implementation which do not necessarily fall into recurring patterns. This shows that the bugs included in BUGSJS are rather diverse in nature, making it ideal for evaluating a wide range of analysis and testing techniques. Our taxonomy seemed more appropriate for the categorization of such logical errors in BUGSJS, with the price that our categories are more high level and independent of the language and the domain of the subject systems.

The most common pattern according to the Hanam et al. scheme, Dereferenced non-values, can also be identified in other related work. Previous work showed that this pattern occurs frequently also in client-side JavaScript applications [5]. Developers could avoid these syntax-related bugs by adopting appropriate coding standards. Moreover, IDEs can be enhanced to alert programmers to possible effects or bad practices. They could also aid in prevention by prohibiting certain actions or by recommending the creation of stable constructs.

Catolino et al. [75] analyzed 1,280 bug reports of 119 popular projects with the aim of building a taxonomy of the types of reported bugs. They devised and evaluated the automated classification model which is able to classify the reported bugs according to the defined taxonomy. The authors defined a three-step manual method to build the taxonomy, which was similar to our approach. The final taxonomy defined in this work contains nine main common bug types over the considered systems: configuration, network, database-related, GUI-related, performance, permission/deprecation, security, program anomaly and test code-related issues. This classification is less suitable to apply to BUGSJS because it is a very high level one, and is not related to JavaScript but to web applications in general.

Li et al. [76] used natural language text classification techniques to automatically analyze 29,000 bugs from the Bugzilla databases of Mozilla and Apache HTTP Server. The authors classified the bugs in three dimensions: root cause (RC), impact (I) and software component (SC). According to RC, bugs can be classified into three disjoint groups (and subgroups): semantic, memory and concurrency. Some of the root cause subcategories are similar to the categories in our taxonomy.

Tan et al. [77] proposed a work that is related to the previous study. They examined more than 2,000 randomly sampled real world bugs in three large projects (Linux kernel, Mozilla, and Apache) and manually analyzed them according to the three dimensions defined by Li et al. [76]. They created a bug type classification model, which used machine learning techniques to automatically classify the bug types.

Zhang et al. [78] investigated the symptoms and root causes of TensorFlow-bugs. They identified the bugs from the GitHub issue tracker using commit and pull request messages. The authors collected the common root causes (which were based on structure, model tensor and API operation) and symptoms (based on error, effectiveness and efficiency) into categories and classified each bug accordingly.

Thung et al. [79] presented a semi-supervised defect prediction approach (LeDEx - Learning with Diverse and Extreme Examples) to minimize the manual bug labeling. The researchers used a benchmark that contains 500 defects from three projects that have been manually labeled based on ODC. In their approach, hand-labeled samples were used to learn and build the model, which uses non-labeled elements to refine the model.
In another study, Thung et al. [80] proposed a classification-based approach used to categorize the bugs into control and data flow, structural or non-functional groups. They performed NLP preprocessing and feature extraction operations on the text mined from JIRA. The resulting data was used to build the model based on Support Vector Machine (SVM).

Nagwani et al. [81] used the bug tracking system to collect textual information and several attributes on bugs. They presented a methodology to bug classification, which are based on a generative statistical model (LDA - Latent Dirichlet allocation) in natural language processing.

8. CONCLUSIONS

The increasing interest of developers and industry around JavaScript has fostered a huge amount of software engineering research around this language. Novel analysis and testing techniques are being proposed every year, however, without a centralized benchmark of subjects and bugs, it is difficult to fairly evaluate, compare, and reproduce research results.

To fill this gap, in this paper we presented BUGSJS, a benchmark of 453 real, manually validated JavaScript bugs from 10 popular JavaScript programs. Our quantitative and qualitative analyses, including a categorization of bugs in a dedicated taxonomy, show the diversity of the bugs included in BUGSJS that can be used for conducting highly-reproducible empirical studies in software analysis and testing research related to, among others, regression testing, bug prediction, and fault localization for JavaScript. Using BUGSJS in future studies is further facilitated by a flexible framework implemented to automate checking out specific revisions of the programs’ source code, running each of the test cases demonstrating the bugs, and reporting test coverage.

As part of our ongoing and future work, we plan to include more subjects (and corresponding bugs) to the benchmark. Our long-term goal is to also include client-side JavaScript web applications in BUGSJS. Furthermore, we are planning to develop an abstraction layer to allow easier extensibility of our infrastructure to other JavaScript testing frameworks.

9. ACKNOWLEDGEMENTS

Gyimesi and Vancsics were supported by project EFOP-3.6.3-VEKOP-16-2017-0002, co-funded by the European Social Fund. Beszédes was supported by the EU-funded Hungarian national grant GINOP-2.3.2-15-2016-00037 titled “Internet of Living Things”. Ferenc was supported by grant 2018-1.2.1-NKP-2018-00004 “Security Enhancing Technologies for the IoT” funded by the Hungarian National Research, Development and Innovation Office. This research was supported by grant TUDFO/47138-1/2019-ITM of the Ministry for Innovation and Technology, Hungary. Mesbah, Stocco and Mazinanian were supported in part by NSERC Discovery and DAS grants.
